Abstract

Identification of paroxysmal atrial fibrillation (AF) can be difficult and undiagnosed AF patients are at high risk of cardioembolic stroke or other complications associated with AF. The aim of this study is to analyze the video photoplethysmographic (vPPG) signal obtained from a video-camera to explore the possibility of discriminating AF from normal sinus rhythm (NSR) and other arrhythmias (ARR). We acquired 24 3-min long face-videos (8 for each rhythm) using an industrial camera. After preprocessing, vPPG signal was extracted using zero-phase component analysis. Diastolic minima were detected and inter-diastolic series obtained. The signals were characterized by time domain indexes, the sample entropy (SampEn); and the shape similarity index (ShapeSim). The time domain indexes and ShapeSim are significantly different when comparing the group of patients with AF or ARR to subjects in NSR. SampEn is significantly higher in AF than in NSR and ARR. From the shape analysis, it can be noted that waves in NSR are more similar than in AF. These preliminary results show the capability of different indexes to capture differences among AF, ARR and NSR. Further studies will help in assessing the performance of the vPPG signal to screen general population.

1. Introduction

In the recent years new monitoring methods have been presented in the literature to detect atrial fibrillation (AF) events by the use of ubiquitous devices such as smartphone [1–3] or wristband device [4]. AliveCor is a single-lead rhythm strip that, combined with a smartphone, is able to detect episodes of AF with 98% of sensitivity. The company Preventicus arises with an app that uses the back camera of the smartphone to individualize AF episodes by the analysis of finger photoplethysmographic (PPG) signal. Another investigation group uses the same technology

to discriminate between AF, sinus rhythm (SR), premature atrial contractions and premature ventricular contractions. The results seemed quite promising, demonstrating a sensitivity of 0.970, specificity of 0.935, and accuracy of 0.951 for real-time identification of an irregular pulse during AF. The app also showed good accuracy for premature atrial contractions 0.955 and premature ventricular contractions discrimination 0.960 [2]. In the video PPG (vPPG) technology, the study of Couderc [5] was the first one that demonstrated the feasibility of AF detection by the use of a contactless technology. The present study aims to enlarge Couderc's study by introducing the detection of other arrhythmias (ARR) that may have the same dangerous consequences of AF.

2. Materials and Methods

2.1. Protocol

Twenty-four patients were enrolled at Ospedale Maggiore Policlinico of Milan, Italy. The study was approved by the internal Ethical Committee of the Hospital. Each patient was asked to sit on a chair and to move as less as possible. The ambient setting included sunlight coming from a window, placed in front of subject's face to avoid possible shadows on his face and an artificial light of neon lamps of the room.

An industrial camera (spatial resolution of 659×494 pixels) positioned on a tripod, was placed in front of the subject at a distance of 1.5 m and connected to a PC workstation. The camera recorded the face of the patient for the whole session of the experiment that lasted 3 minutes. During the acquisition, a 12 leads ECG recorder was used to allow a clinician to determine the type of rhythm of the subject according to three different classes: SR, AF and ARR. According to the clinician classification, 8 patients were in SR, 8 in AF and 8 in ARR during the video recording. Videos were acquired with a frame-rate of 120 frames

per second (FPS) and 8–bits resolutions. Data were saved in RGB, uncompressed, AVI raw format to be processed offline. The camera was equipped with 15 mm fixed focal length lenses.

2.2. Extraction of vPPG

The video recordings were saved in RGB raw format and processed offline to derive the vPPG signal. The video preprocessing includes the three following steps: i) face detection; ii) motion flow; iii) signal extraction.

Face detection and motion flow: Face detection was performed in the first frame by Viola-Jones algorithm [6] and refreshed every 30 s to bootstrap the face tracker [7]. Successively, the face tracking was implemented by using Lucas-Kanade-Tomasi algorithm [8], consisting of two steps: one to choose the best features for tracking and one to align the images. In each frame three regions of interest were considered: forehead (ROI₁), nose (ROI₂) and cheek (ROI₃). These preprocessing steps were implemented in OpenCV.

Signal extraction: A spatial average of pixels intensity was calculated for each ROI in order to have $N_{channels} \times N_{ROI}$ time series. Briefly, within each ROI a spatial average of pixel intensities of each RGB channel was calculated for each frame to generate N raw signals (where N is the number of color channels). The temporal series were first detrended using the technique described on [9] setting the smoothness parameter $\lambda = 400$. A hamming band-pass filter with cutoff frequencies of $f_1 = 0.1$, $f_2 = 5Hz$ was applied to remove high frequencies correlated mainly to artificial light and low frequencies associated to slow movements.

After this preprocessing, to enhance the pulsatile component of the reflected light and reduce the motion noise, the vPPG signal was extracted using the zero-phase component analysis (ZCA) [7]. Since each ROI returns a vPPG signal, the selection of the signal to use for further analysis has been made according to the highest SNR, computed as

$$SNR = 10 * \log_{10} \left(\frac{\int_{f_1}^{f_2} PSD(f) df}{\int_{0.1}^{f_1} PSD(f) df + \int_{f_2}^4 PSD(f) df} \right) \quad (1)$$

where $f_1 = f_p - 0.15$, $f_2 = f_p + 0.15$ and f_p is the pulse frequency (measured in Hz) identified as the highest peak in the power spectral density (PSD).

Figure 1 shows an example of vPPG from three patients in the three rhythms.

As fiducial point for the extraction of pulse-to-pulse interval series, the vPPG diastolic peaks detected by the algorithm of Scholkmann et al. [10] were considered.

2.3. Signal characterization

To characterize the type of rhythm of each patient, different features have been extracted from vPPG signal: three belonging to time domain, sample entropy (SampEn), and the shape similarity index (ShapeSim).

Time domain parameters and SampEn were computed on the inter-diastolic interval series, whereas shape analysis to obtain the ShapeSim index was performed on the vPPG signal.

Variability analysis of the inter-diastolic interval series includes the mean (M), the standard deviation (SD), the root of the mean squared differences of successive intervals, (rMSSD) and the percentage of interval differences of successive intervals greater than 50 ms (pNN50) [11].

Irregularity of the inter-diastolic interval series was assessed by sample entropy (SampEn), that quantifies the unpredictability of fluctuations. The presence of repetitive patterns of fluctuation in a time series makes it more predictable than a time series in which such patterns are absent. SampEn reflects the likelihood that similar patterns of observations will not be followed by additional similar observations. SampEn is the negative natural logarithm of the conditional probability that two sequences of length m that match within tolerance r will also match at the $m + 1$ length. Defining as A the total number of matches of length $m + 1$ and B the total number of matches of length m , SampEn is computed as [12]

$$SampEn = -\ln(A/B) = -\ln(A) + \ln(B) \quad (2)$$

In this study, m was used equal to 1 and r equal to 0.25 times the standard deviation of the series, as commonly used.

To assess wave similarity, each wave is represented as a point of the p -dimensional real space, the normalized waves are points belonging to the p -dimensional unitary sphere. Hence, the morphological dissimilarity between two waves is evaluated by using the standard metric of the sphere to compute their distance [13]

$$D_{i,j} = \arccos(\mathbf{w}_i^N \cdot \mathbf{w}_j^N) \quad (3)$$

where \mathbf{w}_i and \mathbf{w}_j represent the i th and j th normalized waves, and (\cdot) denotes the scalar product. A measure of similarity between waves is obtained by calculating the relative number of similar pairs of waves in the signal. The similarity depends on the threshold used in evaluating the similarity, that is, two waves are considered to be similar when their distance is lower than the threshold. In this study, one pulse in the vPPG signal is considered as wave and the threshold was set to $\pi/2$.

Figure 1. Example of vPPG extracted during (a) sinus rhythm, (b) atrial fibrillation and (c) other arrhythmias.

2.4. Statistical analysis

Kruskal–Wallis one–way analysis of variance was performed to compare the computed parameters during NSR, AF and ARR. If the p-value of the Kruskal–Wallis test was significant, an unpaired Wilcoxon test with Holms correction was applied. A $p < 0.05$ was considered statistically significant. All analyses and statistical tests were performed using MATLAB R2016a (The MathWorks, USA).

3. Results

Figure 2 shows the boxplots of the computed parameters during the three rhythms. All variability parameters can differentiate between NSR and AF, being the variability of inter-diastolic interval series significantly higher in AF than in SR. Two variability parameters (SD and rMSSD) are significantly different also comparing NSR and ARR, being the variability of inter-diastolic interval series significantly higher in ARR than in NSR. SampEn is the only parameter that is significantly different comparing AF with ARR and NSR, being SampEn higher in AF than in NSR and ARR. From the shape analysis, ShapeSim is higher in NSR than in AF and ARR, i.e., waves in NSR are more similar than in AF and ARR.

4. Conclusions

These preliminary results show the capability of different indexes to capture differences among AF, ARR and NSR. Further studies will help in assessing the performance of the vPPG signal to screen general population.
