Abstract

Linear electrocardiographic lead transformations (LELTs) are used to estimate unrecorded ECG leads by applying a number of recorded leads to a LELT matrix. Such LELT matrices are commonly developed using a training dataset. The size of the training dataset has an influence on the estimation performance of a LELT. However, an estimate of the minimal size required for the development of LELTs has previously not been reported.

The aim of this research was to determine such an estimate. We generated LELT matrices from differently sized (from n = 10 to n = 540 subjects in steps of 10 subjects) training datasets. The LELT matrices and the 12-lead data of a testing dataset (n = 186 subjects) were used for the estimation of Frank VCGs. Root-mean-squared-error (RMSE) values between recorded and estimated Frank leads of the testing dataset were used for the quantification of the estimation performance associated with a given size of the training dataset.

The performance of the LELT matrices was, after an initial phase of improvement, found to only marginally improve with additional increases in the size of the training dataset. Our findings suggest that the training dataset should have a minimal size of 170 subjects when developing LELTs that utilise the 12-lead ECG for the estimation of unrecorded ECG leads.

1. Introduction

Linear electrocardiographic lead transformations (LELTs) are used to estimate or derive unrecorded target leads by applying a number of recorded basis leads to a so-called linear ECG-lead transformation matrix [1, 2].

These LELTs are a well-established concept in computerized electrocardiology and are used in a wide range of application areas. For example, LELTs are used for the estimation of the Frank VCG using standard 12-lead ECG [3] or Mason-Linkar 12-lead ECG data [1]. In addition, LELTs are used in reduced lead systems that estimate the 12-lead ECG from a reduced number of monitoring compatible ECG leads [4]. It was recently proposed to utilize LELTs in the performance assessment of modern patch based wearable electrocardiographic devices [5].

The most common form of LELTs utilizes transformation matrices that are designed to be used on ECG data of the general adult population. Such transformation matrices are commonly developed using a training dataset that is composed of ECG data obtained from a number of different subjects. For each of these subjects, one set of target leads and basis leads is included in the training dataset. Transformation matrices of LELTs are typically developed using multivariate linear regression analysis and the target leads and basis leads of the training dataset [1, 3]. The number of subjects whose ECGs are included in the training dataset is commonly referred to as the size of training dataset.

It is desirable that the transformation matrices of LELTs are capable of producing accurate estimates of the target leads for all members of the adult population. The utilization of unrepresentative and small training datasets is known to yield transformation matrices that perform poorly in the general adult population. Training datasets should therefore be of sufficiently large size in an attempt to accurately reflect the statistical relationship between the basis leads and the target leads in the general population.

Recording a large training dataset for the development of a new transformation matrix is potentially a time and cost expensive procedure. It would therefore be desirable to know an estimate of the minimal training dataset size that is required for the development of such a transformation matrix. However, such an estimate has, to the best of our knowledge, not previously been reported in the literature.

The aim of this research is to determine an estimate of the minimal training dataset size required for the development of LELTs. To this end, we assess the estimation performance of transformation matrices developed using training datasets of increasing size. We define the minimal required size of the training dataset as a size, at which only marginally improvements in the performance of a transformation matrix can be achieved through further increases in the size of the training dataset.

2. Material and methods

2.1. Study population

We base our research on a study population of 726 subjects. The study population is composed of 229 normal subjects, 265 subjects with myocardial infarction and 232 subjects with left ventricular hypertrophy. The study population was randomly partitioned into a test dataset ($DTest$) of fixed size and a pool of 540 subjects ($DTrain$) that were used to assemble training datasets of varying size. Table 1 details the composition of $DTest$ and $DTrain$.

Table 1. Composition of test data ($DTest$) and train data ($DTrain$).

	Normal	MI	LVH	Total
$DTrain$	61	66	59	186
$DTest$	171	199	170	540

Notes. ***Normal****, Subjects with no abnormalities in their ECGs;* ***MI****, Subjects with myocardial infarction;* ***LVH****, Subjects with left ventricular hypertrophy.*

2.2. Target and basis leads of the LELTs

The eight independent leads I, II, V1 to V6 of the standard 12-lead ECG were chosen as the basis lead set for the LELTs that were assessed in this research. This was because the standard 12-lead ECG is a popular basis lead set for LELTs. This popularity is due to the fact that LELTs that utilize this basis lead set are compatible with the standard 12-lead ECG, which is the most widely adopted ECG recording format [6].

The heart-vector model [7] of the cardiac electrical activity provided the rational for the utilization of the Frank VCG as the target lead set for the LELTs assessed in this research. Any ECG lead on the body surface can, in accordance with the heart-vector model, be expressed as a weighted sum of the orthogonal X, Y and Z leads used by the Frank VCG. The size of the training dataset that is required for the estimation of the Frank VCG can therefore be regarded as a good indication of the training dataset size required for any other ECG lead.

2.3. BSPM data

One body surface potential map (BSPM) was recorded for each of the 726 subjects in the study population. Each BSPM used in this research contains electrocardiographic data of 120 BSPM leads. A representative average QRS-T complex was calculated for each of the 120 BSPM leads. Three of the 120 leads were recorded from electrodes placed on the right and left wrist and the left ankle (VR, VL and VF respectively). Electrodes situated at 81 anterior and 36 posterior locations were used to record 117 thoracic leads. All thoracic leads were recorded with reference to the Wilson central terminal (WCT). A comprehensive description of the BSPM data and the recording procedure can be found in [8]. A Laplacian 3D interpolation procedure [9] was applied to the 117 thoracic BSPM leads. This was performed to obtain body surface potentials at the locations of the 352 Dalhousie torso [10] nodes.

2.4. Frank VCG data

One Frank VCG [11] was extracted from each of the 726 BSPMs. First, body surface potentials at the A, C, E, F, H, I and M electrode locations of the Frank lead system were extracted from the interpolated BSPM data. Required body surface potentials from body locations that were not a direct subset of the 352 nodes that are used by the Dalhousie torso were obtained using linear interpolation [12]. Second, the body surface potentials at the Frank electrode locations were used to derive the Frank VCG using (1).

$$\boldsymbol{VCG} = [\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z}] = [\boldsymbol{\varphi_A}, \dots, \boldsymbol{\varphi_M}] \cdot \boldsymbol{A^T}. \quad (1)$$

Where $\boldsymbol{\varphi_A}$, $\boldsymbol{\varphi_C}$, $\boldsymbol{\varphi_E}$, $\boldsymbol{\varphi_F}$, $\boldsymbol{\varphi_H}$, $\boldsymbol{\varphi_I}$, and $\boldsymbol{\varphi_M}$ are $n\times1$ vectors that contain n sample values of potentials at the Frank electrode locations A to M respectively, $[\cdot]^{\boldsymbol{T}}$ refers to the transpose of a matrix, n denotes the number of samples in the average QRS-T complex, $\boldsymbol{A}$ is a 3×7 matrix of published coefficients [13] that allow for a derivation of the Frank VCG using the potentials $\boldsymbol{\varphi_A}$ to $\boldsymbol{\varphi_M}$, and $\boldsymbol{VCG}$ is a $n\times3$ matrix containing n sample values of the Frank VCG, the $n\times1$ vectors $\boldsymbol{X}$, $\boldsymbol{Y}$ and $\boldsymbol{Z}$ contain n sample values of the three Frank leads X, Y and Z respectively.

2.5. Standard 12-lead ECG data

One standard 12-lead ECG [6] was extracted from each of the 726 BSPMs. First, body surface potentials recorded at the wrists and ankles were used to calculate the limb leads of the standard 12-lead ECG and the potential at the WCT. Second, the body surface potentials at the electrode locations associated with the precordial leads were extracted from the interpolated BSPM data. Required body surface potentials from locations that were not a direct subset of the 352 Dalhousie torso nodes were obtained using linear interpolation. Third, average QRS-T complexes of the precordial leads were calculated in reference to the WCT using the body surface potentials obtained from the locations of the precordial electrodes.

2.6. Linear regression based ECG lead transformation matrices

The data in $DTrain$ was used to assemble training datasets of different sizes. More precisely, training datasets staring from n = 10 to n = 540 subjects were

generated in steps of 10 subjects. Random sampling with replacement was used to compose 200 different instances for each training set size using the date in $DTrain$. The different instances were used to generate a total of 200 transformation matrices for each training set size. Transformation matrices that allow for the estimation of the Frank VCG from the standard 12-lead ECG were developed using the multivariate linear regression based approach in (2).

$$_{m}\boldsymbol{AVCG_i} = (\,_{m}\boldsymbol{S12L_i^T} \cdot {}_{m}\boldsymbol{S12L_i}\,)^{-1} \cdot {}_{m}\boldsymbol{S12L_i^T} \cdot {}_{m}\boldsymbol{VCG_i}. \quad (2)$$

Where $[\cdot]^{\boldsymbol{T}}$ and $[\cdot]^{-\boldsymbol{1}}$denote the transpose and the inverse of a matrix respectively, $_{m}\boldsymbol{AVCG_i}$ refers to a 12×3 matrix of transformation coefficients that allows for the transformation of the standard 12-lead ECG into the Frank VCG, $_{m}\boldsymbol{VCG_i}$ refers to a n×3 matrix that contains n sample values of the X, Y and Z leads of the Frank VCG, $_{m}\boldsymbol{S12L_i}$ refers to a n×12 matrix that contains n sample values of the eight independent leads I, II and V1 to V6 of the standard 12-lead ECG, $m \in \{10, \dots, 540\}$ denotes the size of the training set and $i \in \{1, \dots, 200\}$ denotes the instance of the training set that was used for the development of $_{m}\boldsymbol{AVCG_i}$.

2.7. Derivation of the target leads

The $_{m}\boldsymbol{AVCG_i}$ matrices were used to derive the target leads of the 181 subjects in $DTest$. This was performed using the approach in (3) and for all transformation matrices with $i \in \{1, \dots, 200\}$ and $m \in \{10, \dots, 540\}$.

$$_{m}\boldsymbol{dVCG_i} = \boldsymbol{S12L} \cdot {}_{m}\boldsymbol{AVCG_i}. \quad (3)$$

Where $_{m}\boldsymbol{AVCG_i}$, m and i are as defined in (2), $\boldsymbol{S12L}$ is a n×8 matrix that contains the n sample values of the QRS-T complex for the eight independent leads of the standard 12-lead ECG of one subject in $DTest$ and $_{m}\boldsymbol{dVCG_i}$ is n×3 matrices that contain the derived leads of the Frank VCG.

2.8. Performance assessment

The average performance of each $_{m}\boldsymbol{AVCG_i}$ matrix was quantified using the data in $DTest$. First, root mean square error (RMSE) values were calculated between the QRS-T complexes of the recorded and the derived target leads. This was performed for each transformation matrix and for each of the 181 subjects in $DTest$. Second, the mean of the 181 different RMSE values associated with each target lead and $_{m}\boldsymbol{AVCG_i}$ matrix was determined. The outcome of this performance assessment was a 200×54 matrix of $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ elements. Where each $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ contains one mean RMSE value for each of the three Frank VCG leads, $i \in \{10, \dots, 540\}$ denotes the size of the training dataset that was used for the development of the transformation matrix associated with the mean RMSE values and $m \in \{1, \dots, 200\}$ denotes the instance of the training dataset that was used for the development of the transformation matrix associated with the mean RMSE values.

2.9. Determination of the minimal required training set size

The minimal required training dataset size was determined separately for each Frank lead using two different criteria.

The first criterion, defined the minimal required training dataset size as the size $i \in \{10, \dots, 540\}$, at which the mean of the $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ values were close to the mean of the $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_{540}$ values associated with the maximum training set size. More precisely, a right-tailed t-test (significance level alpha = 0.05) was used to test whether there was statistical evidence that the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ value associated with a given size i was at least +1% greater than the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_{540}$ value. This test was performed for each size $i \in \{10, \dots, 540\}$. The smallest size i for which this test was not able to reject the null hypothesis, that the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ value associated with a given size i is equal or less than the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_{540}$ value, was considered as the minimal required training set size.

The second criterion, for defining the minimal required training dataset size was based upon reaching 95% of the performance improvement that was observed between the smallest (n = 10 subjects) and the largest (n = 540 subjects) training dataset. First, the difference between the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_{10}$ and the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_{540}$ was calculated. This difference was regarded as the maximal performance improvement that can be achieved when increasing the size of the training set from 10 to 540 subjects. Second, the differences between the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ values for $i \in \{10, \dots, 540\}$ and the mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_{540}$ value were calculated. Third, these differences were expressed as percentage of the maximal performance improvement. Third, a right-tailed t-test (significance level alpha = 0.05) was used to test whether there was statistical evidence that, at a given training size i, more than 5 % of the maximal performance improvement remained unused. This test was performed for each size $i \in \{10, \dots, 540\}$. The smallest size i for which this test was not able to reject the null hypothesis, that the remaining performance improvement was equal or less than 5 % of the maximal value, was considered as the minimal required training set size.

3. Results

A summary of the findings from the analysis of the minimal required training dataset size is provided in Table 1.

Table 1. Minimal required training dataset sizes for each Frank VCG lead and mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ values associate with the minimal and the maximal training dataset size.

Derived lead	criterion[a]	min. size	mean (min. size)[b]	mean (size 540)[c]
X	1% of final value	170	30.4	30.0
	95 % of improvement	170	30.4	
Y	1% of final value	120	30.8	30.3
	95 % of improvement	130	30.7	
Z	1% of final value	130	47.6	46.9
	95 % of improvement	130	47.6	

[a]criterion used for the determination of the minimal required training dataset size; [b]mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ value associated with the minimal required training dataset size; [c]mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ value for a training dataset size of 540 subjects.

4. Discussion and conclusion

This paper reported on the assessment of the minimal training dataset size that is required for the development of LELT matrices. Our analysis was conducted on LELT matrices that transform the standard 12-lead ECG into the Frank VCG. The assessed LELT matrices were intended to be used with members of the adult population. Minimal training dataset sizes of 170 subjects, 130 subjects and 130 subjects were found to be sufficient for the estimation of Frank leads X, Y and Z respectively. Any ECG lead on the body surface can, in accordance with the heart-vector model, be expressed as a weighted sum of the orthogonal X, Y and Z leads. We therefore conclude that a training set size of 170 subjects should be sufficient for the development of LELTs that utilize the 12-lead ECG for the estimation of any ECG lead on the body surface.

A limitation of this research is that transformation matrices were developed and tested on ECGs of three equally represented cohorts (normal subjects, subjects with myocardial infarction and subjects with left ventricular hypertrophy). The influence of the addition or the removal of a patient cohort (from the training and test datasets) on the required minimal training set size was not assessed in this research. We speculate, that the inclusion of additional cohorts with different cardiac disorders will potentially increase minimal required training dataset size.

A further limitation of this research is that it has only assessed the influence of the training dataset size on the mean estimation performance (mean $^{RMSE}_{m}\overline{\boldsymbol{VCG}}_i$ value). This is a limitation as the transformation matrices that were assessed in this research are intended to be used with all members of the adult population. The subject-to-subject variability of the estimation performance is therefore an additional performance metric of LELTs. Future research should therefore assess the influence of the training dataset size on the subject-to-subject performance variability of LELTs.
