## Abstract

*Non-invasive estimation of serum potassium,  $[K^+]$ , and calcium,  $[Ca^{2+}]$ , are of major importance to prevent ventricular arrhythmias and sudden cardiac death, but current ambulatory estimation methods, mostly based on T wave properties, are limited. We present an analysis based on QRS slopes to detect and quantify electrolyte abnormalities in end-stage renal disease (ESRD) patients.*

*We applied principal component analysis to 12-lead electrocardiograms (ECGs) of 29 ESRD patients undergoing hemodialysis (HD). In the first principal component, we analyzed two-minute segments at the end of each HD hour and computed a mean warped QRS complex (MWQRS) representing an optimal average of QRS complexes. We calculated the upward ( $I_{US}$ ) and downward ( $I_{DS}$ ) slope of the MWQRS and we quantified the relative slope changes with respect to the end of the HD session ( $\Delta I_{US}$  and  $\Delta I_{DS}$ ).*

*$\Delta I_{US}$  and  $\Delta I_{DS}$  significantly increased and decreased, respectively, during HD in association with decreasing  $[K^+]$  and increasing  $[Ca^{2+}]$ . The median correlation coefficients of  $\Delta I_{US}$  and  $\Delta I_{DS}$  with the change in  $[K^+]$  were  $-0.84$  and  $0.88$ , respectively. Corresponding correlation coefficients with the change in  $[Ca^{2+}]$  were  $0.78$  and  $-0.91$ . The quantified QRS slope changes were related to both amplitude and duration changes in the QRS complex during HD.*

*Changes in QRS slopes are strongly related to variations in  $[K^+]$  and  $[Ca^{2+}]$  during HD and could be used to monitor electrolyte concentrations in ESRD patients.*

## 1. Introduction

Chronic kidney disease (CKD) affects around 10% of humanity, with high economic cost, increased mortality risk and decreased quality of life [1]. At the final stage of CKD, end-stage renal disease (ESRD) patients present

decreased ability to maintain potassium and calcium homeostasis. Serum potassium ( $[K^+]$ ) and calcium ( $[Ca^{2+}]$ ) levels outside normal ranges, in the form of hypo- or hyperkalemia and hypo- or hypercalcemia, increase the risk for life-threatening arrhythmias and sudden cardiac death [2, 3].

Electrocardiogram (ECG) depolarization and repolarization are known to be affected by variations in  $[K^+]$  and  $[Ca^{2+}]$  [2–4], which has been used to derive markers for continuous monitoring of  $[K^+]$  and  $[Ca^{2+}]$ . In a recently published study [5], several T wave indices are featured as candidates for  $[K^+]$  and  $[Ca^{2+}]$  monitoring. However, the majority of these features do not account for changes in the whole ECG morphology induced by  $[K^+]$  and  $[Ca^{2+}]$  variations but most commonly refer to a specific time point or small portion of the T wave.

In previous studies [6–8], we used time-warping techniques to characterize changes in the shape of the T wave at varying  $[K^+]$  in patients and simulated ECGs. Also, we investigated changes in the nonlinear dynamics of the T wave at varying  $[K^+]$  [9]. A strong relationship was found between investigated linear and nonlinear features of the T wave and  $[K^+]$  [8, 10]. To further improve prediction of electrolyte levels, ECG markers characterizing the T wave could be combined with markers of the QRS complex, which is also known to be affected by varying  $[K^+]$  and  $[Ca^{2+}]$  [2–4].

In this study, we characterized the morphology of the QRS complex by quantifying its upward ( $I_{US}$ ) and downward ( $I_{DS}$ ) slopes during hemodialysis (HD) in ESRD patients. We investigated how changes in  $I_{US}$  and  $I_{DS}$  were related to  $[K^+]$ ,  $[Ca^{2+}]$  and heart rate (HR) variations.

## 2. Methods

### 2.1. Study population

The study population comprised 29 ESRD patients from Hospital Clínico Universitario de Zaragoza (HCUZ), with 48-hour 12-lead ECGs. ECG acquisition started 5 minutes before the onset of HD and lasted 48 hours, as shown in Figure 1 [6–8]. Concurrently, six blood samples were taken at the HD onset, at every hour during the HD session, at the HD end (minute 215 or 245, depending on the patient) and after 48 hours, immediately before the next HD session (Figure 1,  $h_0$  to  $h_{48}$ ).  $[K^+]$  and  $[Ca^{2+}]$  as well as HR were measured at those time points. All patients provided signed informed consent. The ethical committee approved the study protocol (CEICA ref. PI18/003).

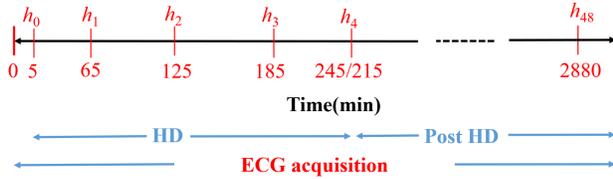

Figure 1. Diagram of the study protocol.  $h_0$  to  $h_{48}$  are the time points (in minutes) for blood sample extraction.

### 2.2. Preprocessing of ECG signals

A wavelet-based algorithm was used for single-lead delineation of the ECG [11]. Baseline wander, muscle and electric noise was attenuated by proper filtering [12]. Spatial principal components (PCs) were obtained by computing the inter-lead auto-correlation matrix of QRS complexes in a stable ECG segment at the end of the HD session. The first PC was used to enhance the QRS complex energy and allow more precise delineation [13]. The locations of the QRS onset, peak and end were identified.

Mean warped QRS complexes (MWQRS) were calculated from aligned QRS complexes at two-minute windows centered at each of the analyzed time points when blood samples were extracted, representing optimal QRS averages [13]. Each MWQRS, calculated at  $h_0$ ,  $h_1$ ,  $h_2$ ,  $h_3$  and  $h_4$ , is denoted by  $x_{QRS}(n)$ .

### 2.3. Measurement of QRS Slopes

From each MWQRS, the upward slope,  $I_{US}$ , and the downward slope,  $I_{DS}$ , were computed [14, 15].  $I_{US}$  and  $I_{DS}$  were defined as the maximum and minimum value of the MWQRS complex derivative denoted by  $x'_{QRS}(n)$ ,

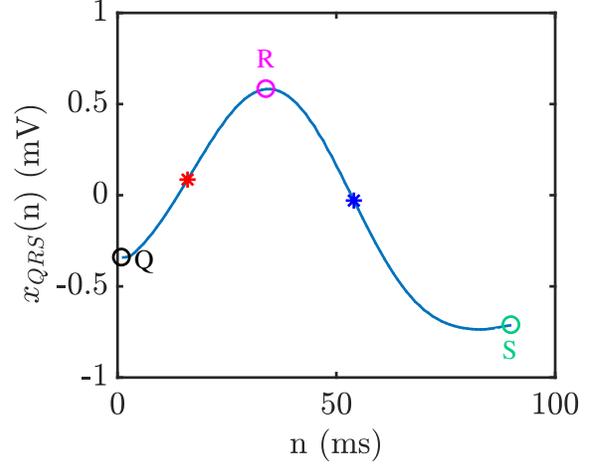

Figure 2. MWQRS from a patient's ECG at the start of HD ( $h_0$ ). Locations of Q (onset of MWQRS), R (peak of MWQRS) and S (end of MWQRS) waves are marked, as well as the locations of maximum and minimum QRS complex derivative (red and blue asterisks, respectively).

respectively:

$$I_{US} = \max_n \{x'_{QRS}(n)\}, \quad n \in \{Q + 1, \dots, R - 1\}, \quad (1)$$

$$I_{DS} = \min_n \{x'_{QRS}(n)\}, \quad n \in \{R + 1, \dots, S - 1\}, \quad (2)$$

with

$$x'_{QRS}(n) = 0.5 \cdot (x_{QRS}(n + 1) - x_{QRS}(n - 1)), \quad (3)$$

and  $Q$ ,  $R$  and  $S$  being the sample locations of the onset, peak and end of the MWQRS, respectively (see Figure 2). For time samples  $n$  at the limits of the QRS upward and downward intervals, the derivative computation in equation (3) require values outside the interval. In such cases, those values are replaced with the ones at the interval limit. Both slopes are expressed in mV/ms.

From the values of  $I_{US}$  and  $I_{DS}$  along HD, we quantified the change in QRS slopes with respect to the end of the HD session ( $h_4$ ) and we denoted them as  $\Delta I_{US}$  and  $\Delta I_{DS}$ .

The Pearson correlation coefficient  $\rho$  and the coefficient of determination  $R^2$  between  $\Delta I_{US}$  ( $\Delta I_{DS}$ , respectively) and the changes in  $[K^+]$ ,  $[Ca^{2+}]$  and RR were computed to assess the strength of electrolyte and heart rate variations on QRS slopes during HD.

## 3. Results and Discussion

Fig. 3 shows the relationship between  $\Delta I_{US}$  ( $\Delta I_{DS}$ , respectively) and  $\Delta[K^+]$  for the 29 patients (panels a-b).  $\Delta I_{US}$  and  $\Delta I_{DS}$  took the smallest and largest values at the beginning of the HD session, corresponding to

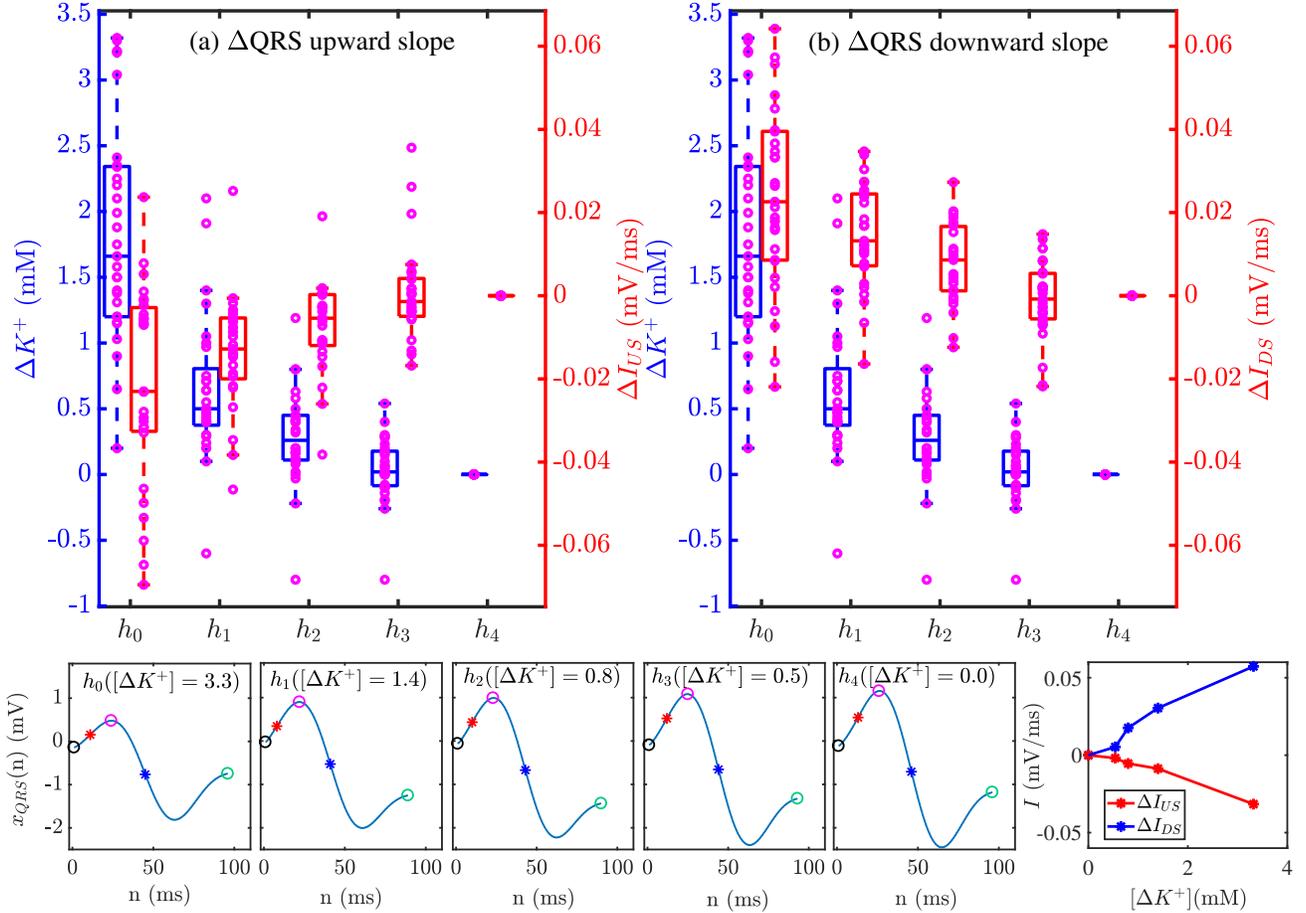

Figure 3. Panels a-b: Relationships of  $\Delta I_{US}$  (red) and  $\Delta I_{DS}$  (red) with  $\Delta[K^+]$  (blue) from MWQRS of 29 ESRD patients. The central line indicates the median, whereas top and bottom edges show the 25<sup>th</sup> and 75<sup>th</sup> percentiles. Each purple dot corresponds to an individual patient. Bottom panels show the MWQRS complexes and QRS slopes variations during HD with  $\Delta[K^+]$  for a patient. Location of Q, R and S waves were marked by black, purple and green circles, respectively. Red and blue asterisks show the locations associated with  $I_{US}$  and  $I_{DS}$  in the QRS complex, respectively.  $\Delta$  denotes change with respect to the end of HD session ( $h_4$ ).

the highest  $[K^+]$  values, respectively. In the bottom panels of Fig. 3, significant changes in the morphology of the QRS complex can be observed during HD. Both QRS markers significantly varied with decreasing  $[K^+]$  during HD, in all the ESRD patients. As shown in the figure, QRS slope changes in ESRD patients were related to both amplitude and duration of the QRS complex.

Correlation analysis was performed to assess the relationship between  $\Delta[K^+]$ ,  $\Delta[Ca^{2+}]$  or  $\Delta RR$  variations (representing changes in  $[K^+]$ ,  $[Ca^{2+}]$  and RR with respect to HD end) and the corresponding changes in  $\Delta I_{US}$  and  $\Delta I_{DS}$ . Figure 4 shows the strong linear Pearson correlation of  $\Delta I_{US}$  and  $\Delta I_{DS}$  with  $\Delta[K^+]$  (median value of  $-0.84$  and  $0.88$ ) and with  $\Delta[Ca^{2+}]$  (median value of  $0.78$  and  $-0.91$ ). However, a poor association was found between both markers and  $\Delta RR$  because the  $RR$  interval

varies much less than  $[K^+]$  and  $[Ca^{2+}]$  during HD in the analyzed ESRD patients. The  $R^2$  values between  $\Delta I_{US}$  and  $\Delta I_{DS}$  with  $\Delta[K^+]$  were  $0.71$  and  $0.79$ , and with  $\Delta[Ca^{2+}]$  these were  $0.66$  and  $0.85$ . As an observation from Figure 4, a wide range of patterns was obtained for the investigated relationships. Computational modeling and simulation of human ventricular electrophysiology could help to gain insight into the sources of such high inter-patient variability.

#### 4. Conclusions

QRS slopes-based markers present remarkable changes with varying  $[K^+]$  and  $[Ca^{2+}]$  in ESRD patients. These results emphasize the importance of characterizing ECG depolarization, in addition to ECG repolarization,

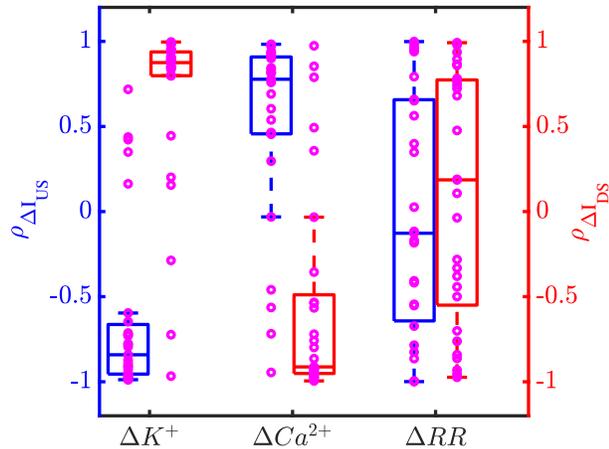

Figure 4. Median (25th/75th percentiles) of  $\rho$  between  $\Delta I_{US}$  (blue) or  $\Delta I_{DS}$  (red) and  $\Delta[K^+]$ ,  $\Delta[Ca^{2+}]$  and  $\Delta RR$ .  $\Delta$  denotes change with respect to the end of HD session.

to monitor hypo- or hyperkalemia and hypo- or hypercalcemia, which could be used to predict arrhythmic events in these patients.
